The numbers in the body of the table represent the area under the normal curve to the left of the standardized z-value. As the standard normal curve is symmetric around the mean of zero, 50% of the area under the normal curve lies to the left of the z-value of zero.

Steps in determining probability values associated with specific z-values of a normally distributed test-statistic:

- Convert the (normally distributed) test statistic into a standardized z-score: $z = \dfrac{x - \mu}{\sigma}$.

- Truncate the obtained z-score to the nearest lower z-value in the table. For example, a z-value of 2.432 can be approximated by the value 2.43 in the table.

- Locate the area under the curve to the left of this z-value in the body of the table at the intersection of the row value representing z-increment of 0.1 and the column value representing z-increments of 0.01. For example, the area under the curve associated with a z-value of 2.43 can be found at the intersection of the row labeled "2.4" and the column labeled ".03": it is 0.9925.

- As the table shows the area under the normal curve *below* the indicated z-value, the probability of obtaining a z-score of 2.43 or *larger* for a normally distributed test statistic is $p \leq .0075$ $(1 - .9925)$.

- For *negative* z-scores, the table entries indicate the area under the normal curve to the right of the z-score. For example, with a z-score of -2.43, the area under the curve to the right of this z-score covers 0.9925.

- To obtain the *two-sided probability* that a test statistic differs from the null-hypothesis value of zero by the *absolute value* of the z-score in either direction, we multiply the one-sided probability by 2, as the normal distribution is symmetric. For example, the probability of obtaining a z-score of $+2.43$ or larger or -2.43 or smaller equals $p \leq .015$ $(.0075 \times 2)$.
